

2.

Because each iteration, even MPC will get the whole predicted trajectory which is base on our control sequence, We only take one control input for this iteration.

In next iteration, MPC will solve base on the new state after our control input.

3.

The difference will decrease.

When $Q_f = Q$, there is only a state penalty for terminal state but no long time cost start from x_N .

MPC only optimize the steps in his horizon

But the final state of DARE include more information about long time cost.
